Show that if a sparse language is NP-complete, then $P = NP$.

Proof:

Let $L \in NP$ be a sparse, complete language.

Since L is complete in NP, then there exists a reduction from 3-SAT to L in polynomial time. Let $R(x)$ be the part of that reduction which transforms the 3-CNF boolean formula from 3-SAT to an input to L .

Since L is sparse but 3-SAT is not, then there will be some $x_1, x_2 \in 3\text{-SAT}$ where $R(x_1) = R(x_2)$. Let $l = |L| + 1$. Then given any boolean formulas f_1, f_2, \dots, f_l , consider $R(f_1), R(f_2), \dots, R(f_l)$. There are two cases:

- If $\forall i, j$ then $R(f_i) \neq R(f_j)$, then $\exists k \in [1, l]$ such that $R(f_k)$ is unsatisfiable. This is true because under the reduction f is satisfiable iff $R(f)$ is in L , and by the pigeonhole principle, only $l - 1$ members of $R(f_1), R(f_2), \dots, R(f_l)$ can be in L , so one must be unsatisfiable.
- If $\exists i, j$ such that $R(f_i) = R(f_j)$, then f_i and f_j are either both satisfiable or both unsatisfiable.

We will now construct an algorithm for a TM M which can solve 3-SAT in polynomial time. The algorithm will construct a tree T of different variable assignments. Each level i of T will represent boolean formulas where variable i 's assignment is considered. Each node in level $i - 1$ has 2 branches, one where variable i is true and one where it is false. At any level, if we have a boolean formula that is satisfiable with the variable assignments at that node then the original formula is satisfiable. Also, if no boolean formulas at a level are satisfiable, then the original formula is unsatisfiable.

With n variables as input, T will have a maximum height of n and 2^n leaves. Constructing and searching this tree as it stands would take exponential time so M must prune branches at each level with more than l nodes. Let M also use the following steps to prune T as it is constructed:

1. Construct l boolean formulas $g_2 = f_1 \vee f_2, g_3 = f_1 \vee f_3, \dots, g_{l+1} = f_1 \vee f_{l+1}$
2. Run R against g_1, \dots, g_l . Since there are l different results of the transformation, we have one of our two previous properties. Consider the following cases:
 - (a) $\forall i, j$ then $g_i \neq g_j$. In this case, f_1 must be unsatisfiable. If it were satisfiable, then all g must be satisfiable which we know cannot happen. Thus we prune all the f_1 node since its unsatisfiability will not help us to determine if the overall formula is unsatisfiable.
 - (b) $\exists i, j$ such that $g_i = g_j$. Then we can prune either f_i or f_j with the same result. This is because of the two following cases:
 - i. If f_1 is satisfiable, then the original formula is satisfiable so we don't need both f_i and f_j to determine that.
 - ii. If f_1 is unsatisfiable, then f_i is satisfiable iff f_j is, so either node can be removed without changing whether our original formula is satisfiable.

Following the previous rules for pruning T , will result in a tree with a maximum depth of n and a maximum width of $n * l$ at each level. Thus the tree will have a maximum of $n^2 * l$ nodes which is polynomial to construct and search. Finally, M decides 3-SAT in polynomial time.

Since 3-SAT is decidable in polynomial time, $3\text{-SAT} \in P$. Since 3-SAT is also NP-complete, all languages in NP are in P. So we have the final results that L being NP-complete and sparse implies that $P = NP$.

a

Construct a TM N with the following behavior:

On input x :

1. Run M on x .
2. If $M(x) = 1$, accept.
3. If $M(x) = 0$, reject.
4. If $M(x) = ?$, repeat step 1.

$L(N) \in ZPP$ because it uses a probabilistic TM M , but has zero-sided error. If M outputs 1 or 0, then N finishes computation. But since M has a chance of outputting $?$, the runtime of N is probabilistic, because N only halts when M does not output $?$. $P(N \text{ loops once}) = \frac{1}{2}$, $P(N \text{ loops twice}) = \frac{1}{4}$, $P(N \text{ loops } n \text{ times}) = \frac{1}{2^n}$.

b

Show that $ZPP = RP \cap coRP$

First we show that $ZPP \subseteq RP \cap coRP$

Let $L \in ZPP$.

Then \exists probabilistic TM T and integer t such that:

- $\forall x T(x)$ runs in time $|x|^t$ for all but finitely many inputs
- $x \in L \Rightarrow \text{Prob}(T(x) \text{ accepts}) = 1$
- $x \notin L \Rightarrow \text{Prob}(T(x) \text{ rejects}) = 1$

Using T , we construct a TM Z as follows:

On input x :

1. Run T on x for $100|x|^t$ steps.
2. If T halted, output its answer
3. Otherwise reject

Now we have a TM Z such that if $x \in L$, Z accepts with probability $\leq \frac{1}{100}$ and, if $x \notin L$, Z accepts with probability 0. Additionally, because T runs in polynomial time, so does Z .

Therefore $L(Z) \in RP$ and $ZPP \subseteq RP$.

Moreover, using the fact that ZPP is closed under complement, we get that $ZPP \subseteq coRP$ by switching acceptance and rejection in our definition of Z .

Therefore $L(Z) \in coRP$ and $ZPP \subseteq coRP$.

Thus $L(Z) \in RP \cap coRP$ and $ZPP \subseteq RP \cap coRP$.

Next we will show $RP \cap coRP \subseteq ZPP$:

Let $L \in RP \cap coRP$

Then \exists probabilistic TM M and integer m such that:

- $\forall x M(x)$ runs in time $|x|^m$ for all but finitely many inputs
- $x \in L \Rightarrow \text{Prob}(M(x) \text{ accepts}) > 0.6$
- $x \notin L \Rightarrow \text{Prob}(M(x) \text{ rejects}) = 1$

There also exists a probabilistic TM N and integer n such that:

- $\forall x N(x)$ runs in time $|x|^n$ for all but finitely many inputs
- $x \in L \Rightarrow \text{Prob}(N(x) \text{ accepts}) = 1$
- $x \notin L \Rightarrow \text{Prob}(N(x) \text{ rejects}) > 0.6$

Using M and N , we construct a TM O similar to the TM described in part a as follows:

On input x :

1. Run M on x .
2. If $M(x) = 1$, output 1.
3. Otherwise, run N on x .
4. If $N(x) = 0$, output 0.
5. Otherwise output ?.

Clearly O runs in polynomial time and, by part a, $L(O) \in ZPP$

Therefore $RP \cap coRP \subseteq ZPP$

Thus, $ZPP = RP \cap coRP$
